1. Introduction

Mobile sensor cloud is the novice research area emerged with the concepts of Mobile sensing and Cloud Computing. The communication among sensor nodes using Internet is often a challenging issue. Cloud Computing is a good solution for this. Sensor cloud collects data from physical mobile sensors and computes the large scale data. Cloud enables on-demand service, resource storage and virtualized instances to the end users. It also provides cost effective services which is an added advantage to users as many of them cannot afford a physical sensor for their small usage. Here the cloud provides the control to physical sensors on pay per use basis. Mobile Sensors are not fixed at a particular location; they have the capability to move around. This feature of the sensors supports the proposed cloud engine system. Cloud should have the capability to manage the mobility of such sensors so that the end users feel like they have continuous on-demand access of the physical sensors.

1.1 Motivation

Around half of the American population live in areas with air, which is at dangerous levels of pollution for breathing. Top five of the most polluted regions are in our California state [11]. Apart from this around 17.7 million people have asthma [12]. This is a critical issue that has to be given enough attention to. Also there are not many applications that tells the real-time level of pollution of a particular area. This kind of application can help people choose if an area is safe for them to travel or not and becomes indispensable for asthma patients.

This is the noble motivation behind our project. This project is about designing a air control system for detecting any accidental smoke due to any leakage, forecasting and analyzing weather conditions of the city using physical sensors deployed on the streets and the powerful mobile sensors inbuilt in today's smartphones or drones. Set of virtual sensors are set up which resemble physical sensors, these virtual sensors are dynamic and provide automatic provisioning of services. A user interface consisting of user dashboard is provisioned by sensor cloud for monitoring and administrating the virtual sensors like adding and deleting sensors etc.

1.2 Project Outcomes

The project can be divided into the following components:

Mobile Sensor management:

This service enables users to subscribe, modify or unsubscribe different available mobile sensors. The admin can add, delete or modify a sensor. This service acts as an interface between admin, users and mobile sensor clusters. The Connectivity and configuration is also taken care in this module.

Mobile Sensor Monitoring:

This module enables admin and user to monitor the user statistics, sensor availability and billing.

Mobile sensor Provisioning:

Mobile sensor network connection management, Connection service, Mobile sensor owner registration, Mobile sensor Connection and configuration service are included in this service.

Scalability support:

Load balancing in sensor clouds is a technique that distributes the excess dynamic local workload evenly across all the nodes. It is used for achieving a better service provisioning and resource utilization ratio, hence improving the overall performance of the system. In our project, incoming service request are coming from different users are received by the load balancer and then distributed to the virtual sensor cluster for the proper load distribution.

Dashboard User Interface:

User can add, delete and modify the sensor data using this web based user interface. A user can visualize the collected data, admin can use this interface to configure and control mobile sensor data.

2. Infrastructure Analysis and Design

2.1 System Architecture Design

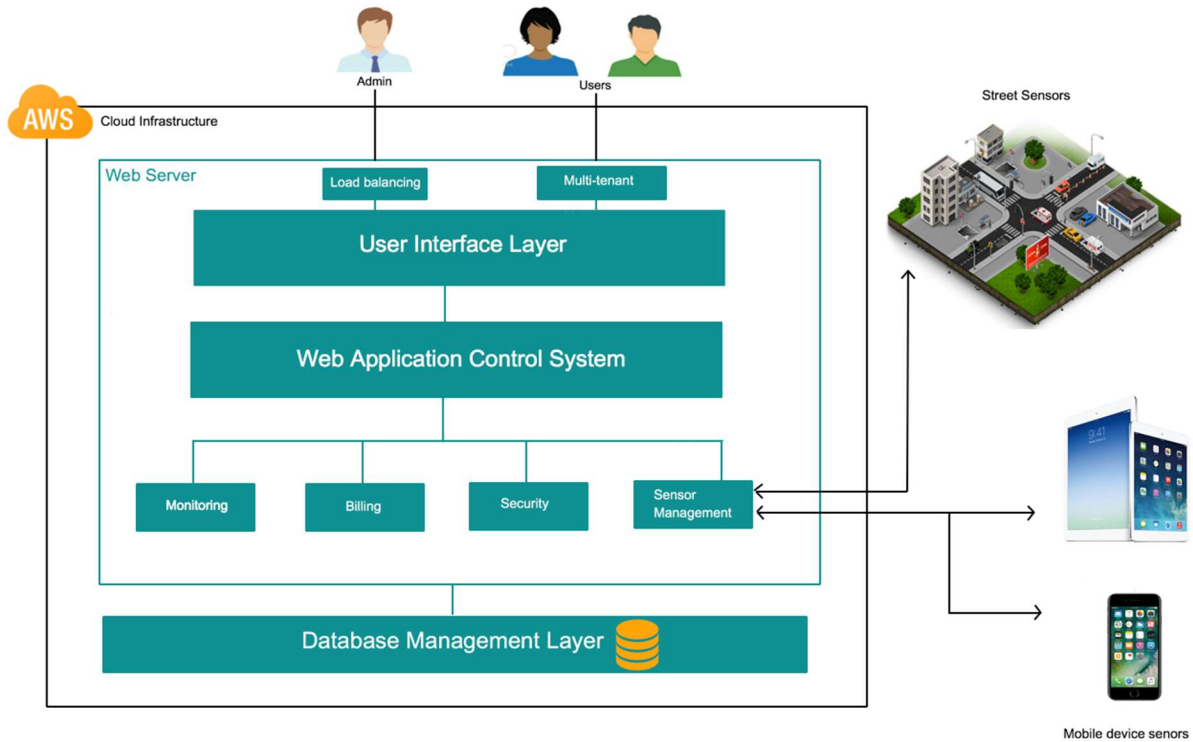

Figure 1: System Architecture Design

The architecture design of our project is as shown in Figure 1. The entire application is hosted on AWS EC2 server. The users and admin both interact with the UI layer. In order to handle heavy traffic and to serve many clients, there will be a load balancer and the system will support multi-tenant operations. The request will then be received by the core application layer to monitor, compute and respond back to the users. The sensor data will be collected from the sensors on the street as well as mobile sensors such phones, tablets etc. The application layer will also have a MySQL database to persist user, application and sensor information.

2.2 Deployment Infrastructure

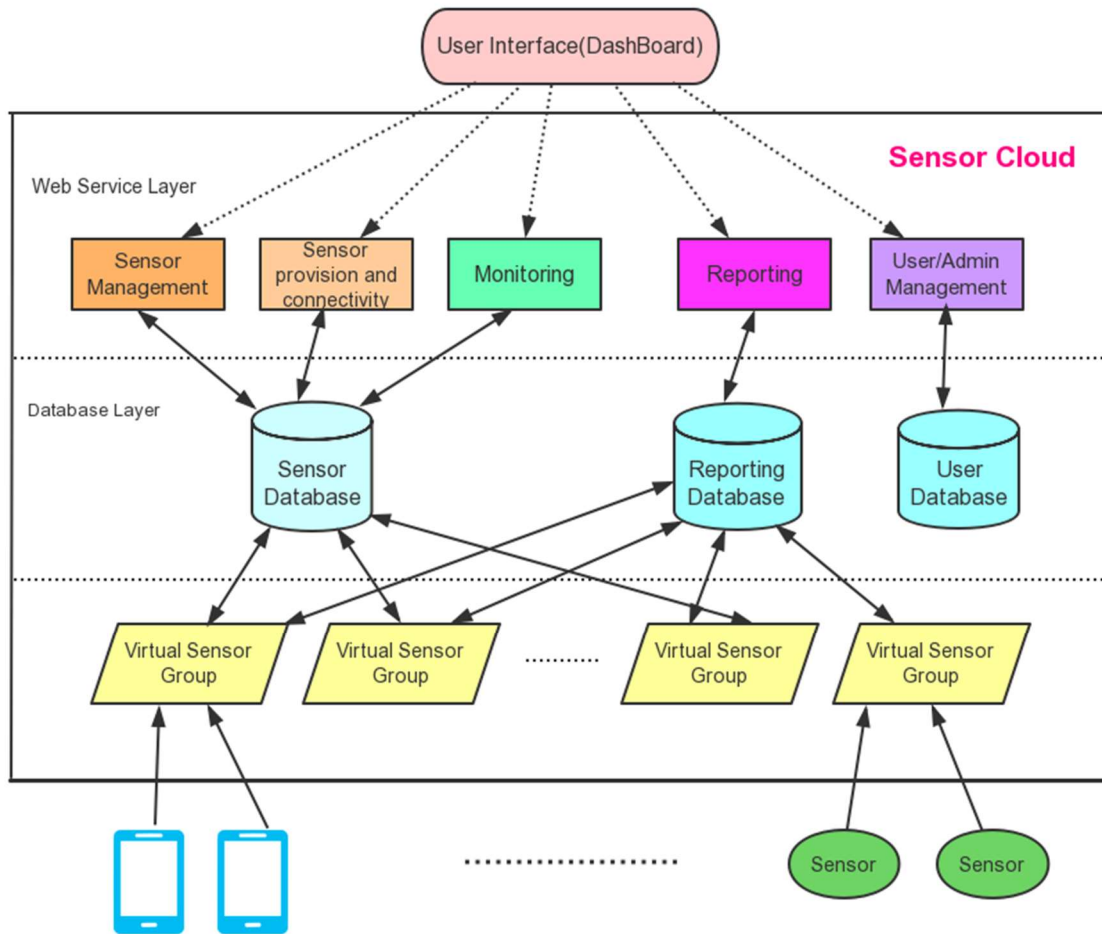

Figure 2: Deployment design diagram

The Figure 2 demonstrates the deployment flow path of the sensor cloud. User or administrator using sensor cloud service through dashboard user interface. Sensor management allow users to register, configure, and manage different types of sensor. Mobile virtual sensor resources are automatic on demand provision to users. Mobile sensor provision in charge of sensor cluster allocation, resource collection and data storage. Mobile sensor monitoring allows users to track the sensors' status, type and other detail information. Mobile reporting or we could call billing service provides the resource usage information and billing statement for users.

2.3 Component based UML Design

The main goal of the UML diagram shown below is to define each functional components of the Cloud system. The path taken by each action or task is also clearly shown. The main sub functions of each component is also briefed.

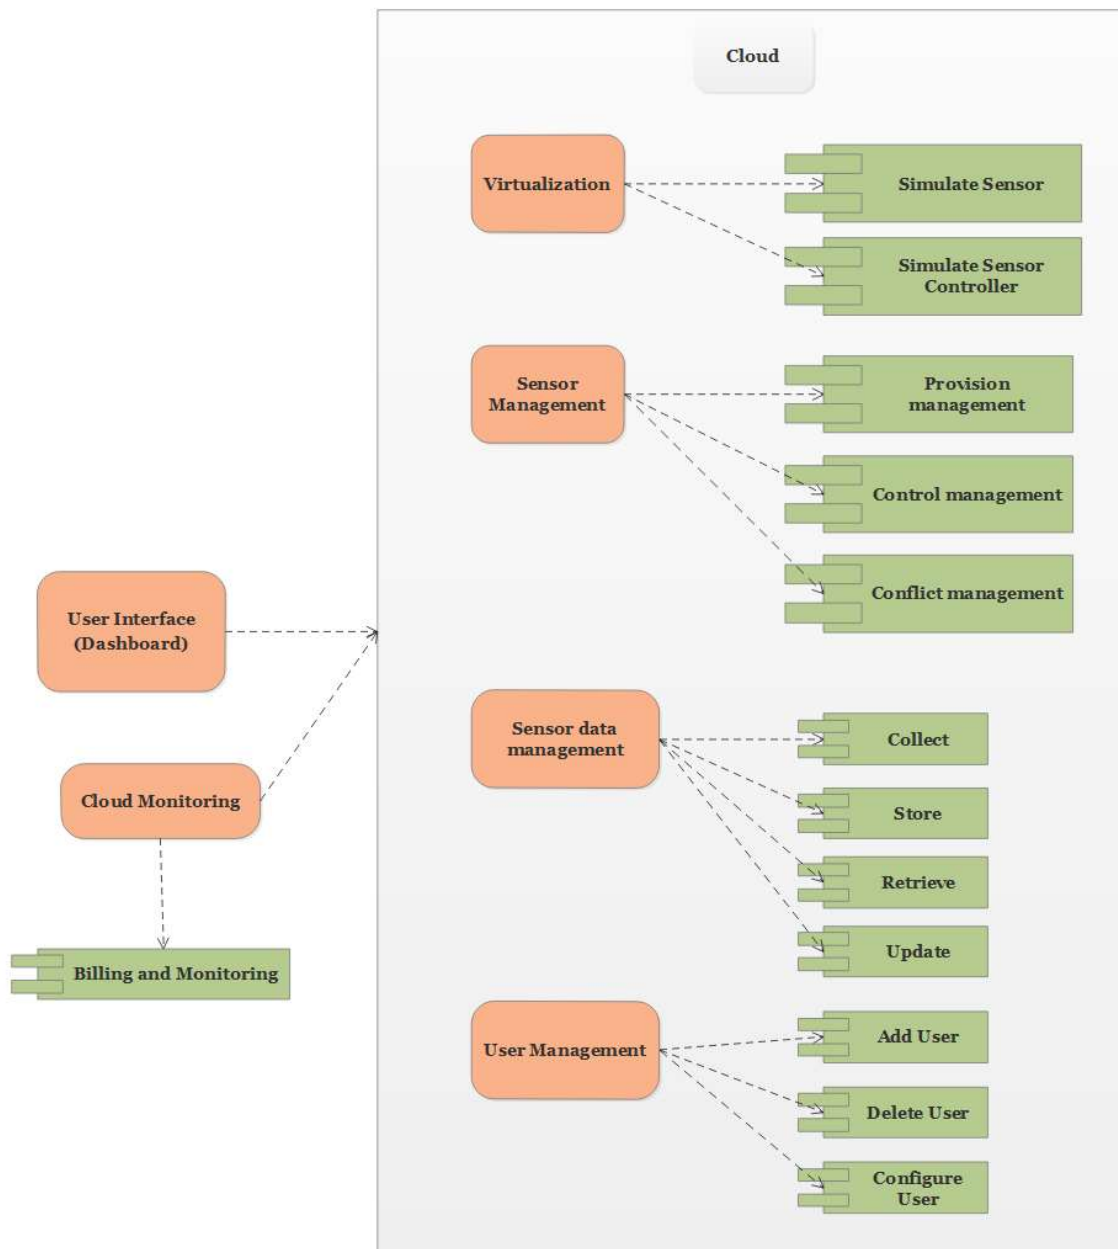

Figure 3: Component design diagram

2.4 Class Design

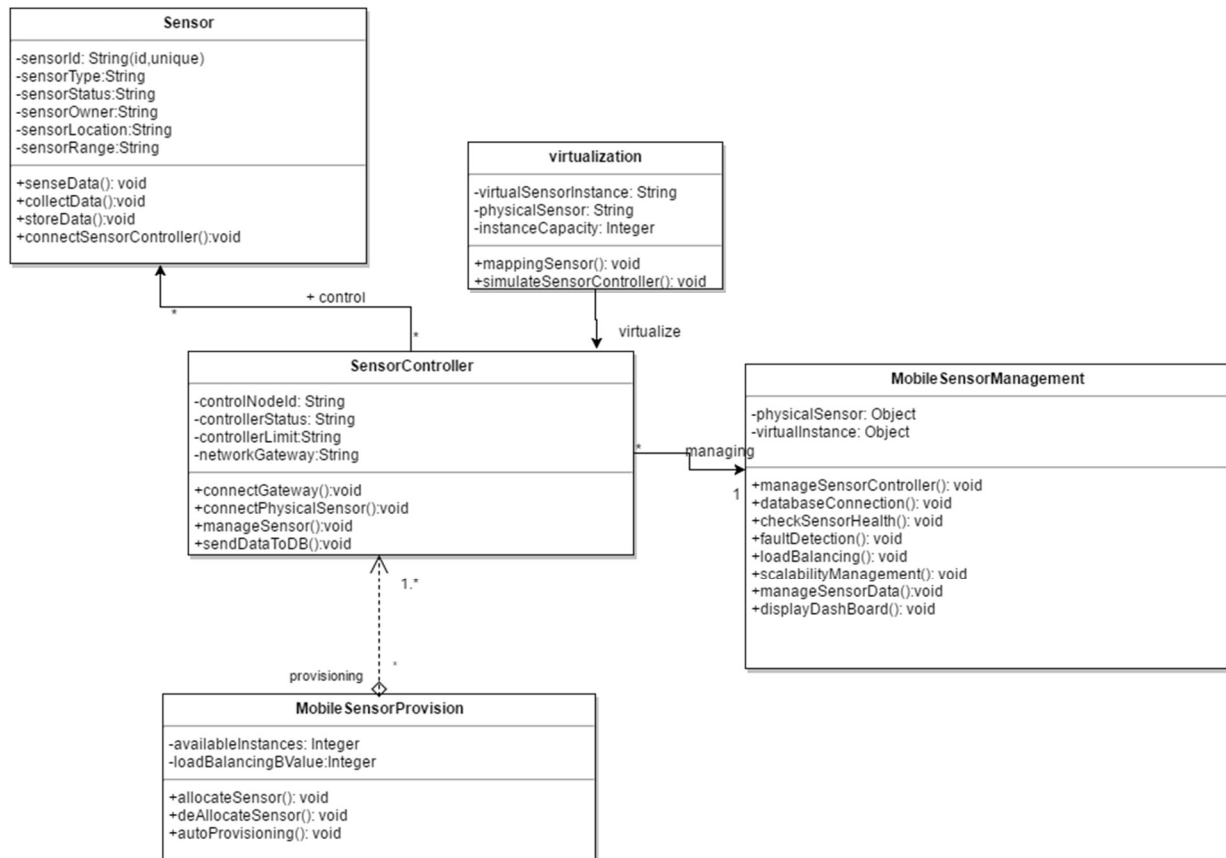

Figure 4: Class Design

3. Function Component Design

3.1 Mobile Sensor Management

The mobility feature of our sensors can be implemented by putting them on a drone. Since, we work on the cloud platform part of this application, we will stay focused on the same. From user perspective, Sensor cloud system is a multi-tenant platform which permits multiple user to register and request virtual sensor resources on demand, without impacting each other. User joining the sensor cloud first need to create account and establish authentication mechanism. After that, users are able to register and request sensor resources on the assigned logic space of the sensor cloud. When the user submits the registration request with the configuration, the sensor management system is able to prepare the required virtual sensor resource automatically. When the user wants to edit or remove certain sensors from the cloud, the sensor management system is able to update the association of those sensors upon request.

Figure 5: user request sensor workflow

3.2 Mobile Sensor Monitoring

The function of mobile sensor monitoring is to provide user or administrator the real-time information about sensor (for example: sensor status, location, type etc.) and resource usage (including CPU utilization, network usage, storage usage etc.). All that information is stored in the database and will be processed and displayed to users through the dashboard. In order to make the information easier to read, the comparison metrics and statistical model will be implemented before displaying to dashboard. Overall, the monitoring system consists of four parts:

- Sensor data collector
- Data processing and visualization
- Resource usage collector
- Resource usage reporter

3.3 Mobile Sensor Provision

Mobile sensor provision is the allocation of a cloud provider's sensor and computing resources to a user. When a user sends a request to the mobile sensor cloud, it must create the appropriate number of virtual sensor resources and allocate it to support them. The process is conducted in several different ways: advance provisioning, dynamic provisioning and user self-provisioning.

With advance provisioning, the cloud user contracts with the provider for services and the provider prepares the appropriate resources in advance of start of the service. The user is charged a flat fee or is billed on a monthly basis. Dynamic provisioning provides users a pay-per-use model by allocating resources when user request and removes them when user do not need. With user self-provisioning, the user purchases resources through a web form, creating a customer account and paying for resources with a credit card. The cloud provider's resources are available for customer use within hours, if not minutes. In our project, we will adopt advance provisioning.

3.4 Scalability Support

Figure 6: load balancing diagram

Load Balancer acts as a reverse proxy and distributes network or application traffic across a number of servers. In our project, we host our application on AWS. AWS provide a service named Elastic Load Balancing. ELB is a load balancing solution that automatically scales its request-handling capacity in response to incoming application traffic. It increases the availability of our application by configuring the load balancer to route traffic to EC2 instances. You can add and remove instances from your load balancer as your needs change, without disrupting the overall flow of requests to your application.

Create a New Load Balancer

DEFINE LOAD BALANCER

CONFIGURE HEALTH CHECK

ADD EC2 INSTANCES

REVIEW

This wizard will walk you through setting up a new load balancer. Begin by giving your new load balancer a unique name so that you can identify it from other load balancers you might create. You will also need to configure ports and protocols for your load balancer. Traffic from your clients can be routed from any load balancer port to any port on your EC2 instances. By default, we've configured your load balancer with a standard web server on port 80.

Load Balancer Name:

e.g. MyLoadBalancer

Create LB inside:

EC2

Listener Configuration:

Load Balancer Protocol	Load Balancer Port	Instance Protocol	Instance Port	Actions
HTTP	80	HTTP	80	Remove
HTTP		HTTP		Save

Continue

Figure 7: Load balancer configuration

For load balancing algorithm, we use a currently prevalent load balancing algorithm Round Robin algorithm in our project. It uses the round robin scheme for allocating user's service request. The virtual sensor resources are provisioned to the users on first-cum-first-serve basis and scheduled in time sharing manner. It means each virtual sensor cluster receive some traffic to avoid some server is heavily loaded or someone is lightly loaded.

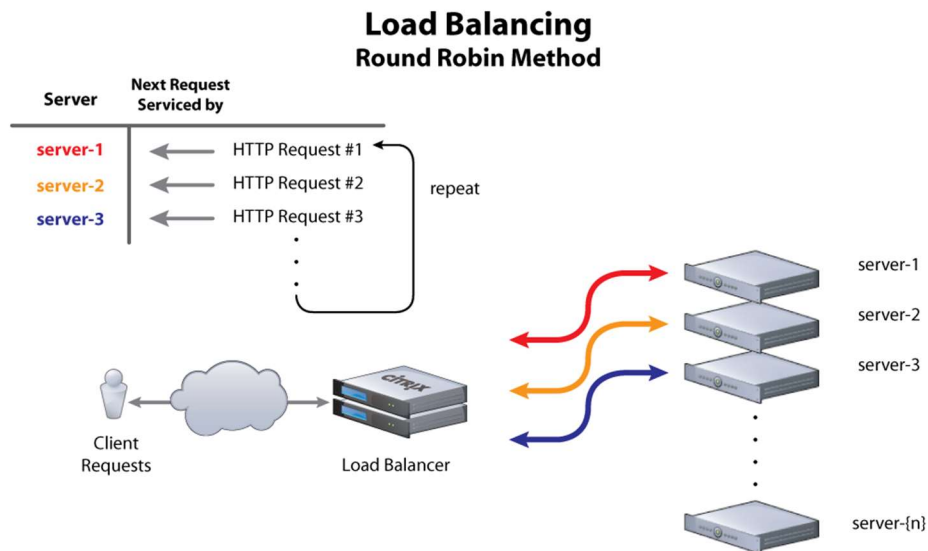

Figure 8: Round Robin load balancing algorithm

4. Implementation

4.1 Project Technologies

- Front end technology: Node.js, AngularJS, Bootstrap
- AWS infrastructure: EC2 Service, Elastic load balancer, CloudWatch
- Storage Service: MySQL

Figure 9: Application Layout

We are using Node.js to create server environment. AngularJS is used for front-end designing. Sensor data, user and admin data, billing details are all stored in MySQL database. Amazon's Elastic load balancer is used to provide the scalability and load balancing feature for our application.

4.2 Why AWS?

AWS has been the choice of cloud provider for various reasons as listed below:

- Flexibility to port application and data to other cloud providers
- Easy to use for beginners
- Cost-effective
- Reliable
- Secure
- Scalable

6. Conclusion

The main goal of the project was to create a Mobile sensor cloud application that helps users to subscribe to and manage sensors, with a pay-as-you-go billing model. The application supports virtualization, provision, management, monitoring, billing and an interactive well-designed user interface for user dashboard. It runs on the AWS platform running efficiently with the help of the services provided by AWS. Load balancing has been implemented with AWS ELB, which uses round-robin algorithm to perform balancing.
